The incidence of bullous pemphigoid is increasing recently, partly due to the increase of the use of certain culprit drugs, such as dipeptidyl peptidase-4 (DPP-4) inhibitors, psychotropic drugs, and checkpoint-inhibitors.\textsuperscript{1} DPP-4 inhibitors, a class of oral hypoglycemics, block the enzyme dipeptidyl peptidase-4, and can be used to treat diabetes mellitus type 2. Association of bullous pemphigoid and mucous membrane pemphigoid with DPP-4 inhibitors in patients with diabetes has been recently demonstrated.\textsuperscript{2, 3} Bullous pemphigoid associated with DPP4 inhibitors (DPP4i-BP) tends to show clinically non-inflammatory phenotypes and be negative for the BP180 NC16A domain, but positive for full-length BP180.\textsuperscript{4} On the other hand, several cases of DPP4i-BP have been reported to be positive for anti-BP180 NC16A domain antibodies and show inflammatory phenotypes with prominent erythemas.\textsuperscript{5}

A 90-year-old Japanese man was referred to us for evaluation of itchy blistering skin lesions on the limb and trunk that had developed one month before. He had been diagnosed with mild diabetes mellitus for 30 years, which had been untreated. At the first visit to our hospital, chemiluminescent enzyme immunoassay (CLEIA) was positive for anti-BP180 NC16A antibodies (265.3 U/ml, with the standard normal value of <9 U/ml). Histopathology of the skin
biopsy from a bulla demonstrated subepidermal blister with infiltrates of eosinophils. Direct immunofluorescence analysis showed a linear deposition of complement C3 at the basement membrane zone. We diagnosed the patient with bullous pemphigoid and started treatment with prednisolone 30 mg/day (0.44 mg/kg/day) and minocycline 200 mg/day. Ten months after the first visit, when the skin condition was stable with prednisolone 8 mg/day, sitagliptin, a member of the DPP-4 inhibitors, was started by the patient’s primary care doctor. One month later, multiple infiltrative erythemas, erosions, and blisters developed on the entire body (Fig. 1). The anti-BP180 NC16A antibody titer elevated to 538.2 U/ml. We stopped the administration of sitagliptin and started treatment with prednisolone 35 mg/day and minocycline 100 mg/day. Despite this, new blisters appeared and erythemas continued; then, we started intravenous immunoglobulin therapy (30 g/day; 0.44 mg/kg/day, for 5 days). The skin lesions gradually improved with a decrease in the titers of anti-BP180 NC16A domain antibodies. However, although the dose of steroid was tapered, the skin lesions were refractory and could not be completely suppressed. Unfortunately, after 37 weeks after the exacerbation by sitagliptin, the patient developed sepsis with disseminated intravascular coagulation and finally passed away from multiple
organ failure. The whole disease course of this case is illustrated in Fig. 2.

In the present case, bullous pemphigoid that had been stable with a low dose of steroid showed exacerbation of exanthemas with a rapid rise in the level of anti-BP180 NC16A autoantibodies one month after administration of a DPP-4 inhibitor. To our knowledge, such cases have never been reported. DPP-4 inhibitors are generally safe and can be used even for elderly patients with diabetes mellitus. In bullous pemphigoid cases, particular care is required in the selection of the drugs for diabetes mellitus.
